Summary

Tumor cells can evade chemotherapy by acquiring resistance to apoptosis. We investigated the molecular mechanism whereby malignant and nonmalignant mammary epithelial cells become insensitive to apoptosis. We show that regardless of growth status, formation of polarized, three-dimensional structures driven by basement membrane confers protection to apoptosis in both nonmalignant and malignant mammary epithelial cells. By contrast, irrespective of their malignant status, nonpolarized structures are sensitive to induction of apoptosis. Resistance to apoptosis requires ligation of β 4 integrins, which regulates tissue polarity, hemidesmosome formation, and NF κ B activation. Expression of β 4 integrin that lacks the hemidesmosome targeting domain interferes with tissue polarity and NF κ B activation and permits apoptosis. These results indicate that integrin-induced polarity may drive tumor cell resistance to apoptosis-inducing agents via effects on NF κ B.

Introduction

Apoptosis is essential for immune surveillance and for the efficacy of tumor therapy (Costello et al., 1999; Rathmell and Thompson, 2002). Although considerable progress has been made toward understanding how apoptosis is executed at the cellular level (Adams and Cory, 1998; Thornberry and Lazebnik, 1998), less is known about what regulates apoptotic decisions and how apoptotic agents could selectively target the tumor tissues.

The site of tumor cell metastasis is influenced by the composition of the extracellular matrix (ECM) and the integrins expressed by the tumor cells (Pignatelli and Stamp, 1995). Despite the fact that tumors overexpress ECM-degrading proteases, aggressive tumors often make excess basement membrane (BM) and have abundant β 4 integrins (Tagliabue et al., 1998;

Rabinovitz and Mercurio, 1996). This paradox suggests that, in some cases, ECM adhesion may foster tumor progression rather than tumor inhibition (Tani et al., 1997; Pfohler et al., 1998). Interactions between tumor cell integrins and adhesion molecules in the ECM microenvironment may drive the selection of treatment-resistant tumors (Nicolson, 1988; Singh et al., 1997; Van Riet et al., 1998; Puduvali, 2001). However, the rate at which tumors can acquire resistance to treatment in vivo argues that mechanisms, functioning independently of genetic selection, must also operate to drive the genesis of apoptosis resistance in metastatic tumors.

The tissue ECM may modify the responsiveness of tumors to exogenous apoptotic stimuli. Adhesion to ECM rapidly and reversibly modifies the responsiveness of myeloma and lung tumor cells to chemotherapeutic drugs (Damiano et al., 1999; Sethi et al., 1999). Tumor cells selected for their drug resistance

SIGNIFICANCE

Here we used a 3D model of nonmalignant and malignant human breast epithelial cells that could be repeatedly and reversibly organized into polarized tissue-like structures to study how normal tissues and some tumor cells resist apoptotic cell death by chemotherapeutic agents and immune regulators. We show that, regardless of the genetic makeup, the rate of growth, or the malignant status, resistance correlates with ECM composition, hemidesmosome-dependent polarity, and NF κ B activation. Our model sheds light on the endogenous activation of this pathway in epithelial tissues. These data indicate the critical importance of tissue architecture in resistance to apoptosis, have important implications for how tumor cells may become dormant, and offer possible chemotherapeutic strategies.

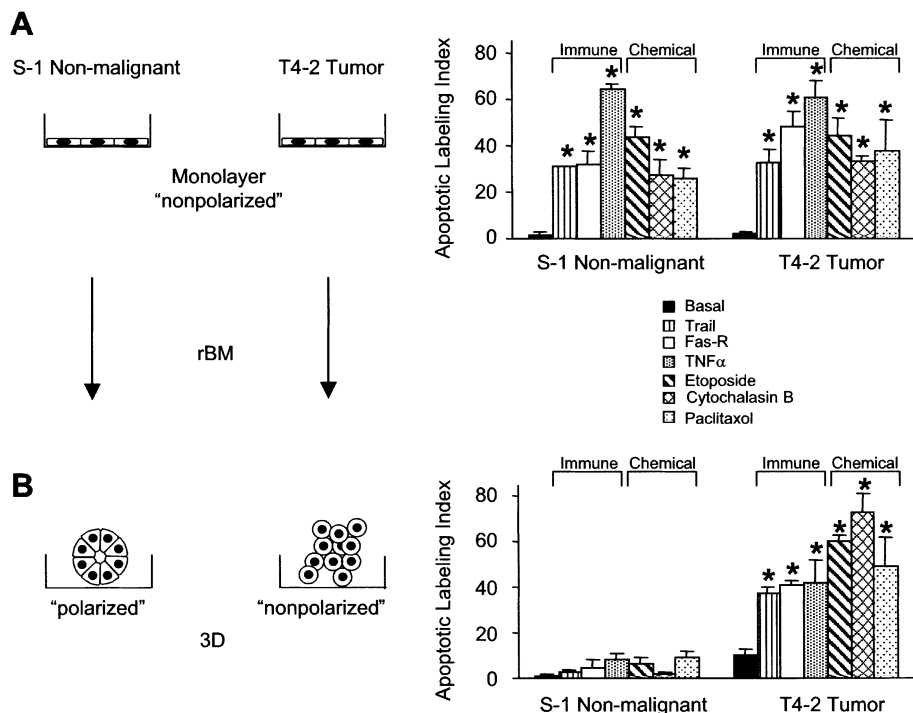

Figure 1. Only nonmalignant cells within mammary acini are resistant to apoptosis

Apoptotic labeling indices calculated for S-1 and T4-2 cells treated with Trail peptide (1 μ g/ml), anti-FAS mAb (IgM CH-11, 2 μ g/ml), TNF- α (100 nM), etoposide (50 μ M), cytochalasin B (1 μ M), or paclitaxol (120 nM). Cells were treated (A) as monolayers on a thin coat of collagen I for 24 hr or (B) as 3D structures in rBM for 96 hr. Results are the mean \pm SEM of 3–5 separate experiments, each with duplicates or triplicates.

in monolayer cultures develop changes in cell adhesion and integrin expression (Nista et al., 1997; Narita et al., 1998). Tumor cells grown as three-dimensional (3D) multicellular spheroids rapidly acquire and sustain a multidrug-resistant phenotype in response to acute drug treatment (Durand and Olive, 2001; Kerbel 1994), exhibit modified adhesion (Hauptmann et al., 1995; St. Croix et al., 1998), and secrete ECM proteins (Santini and Rainaldi, 1999). This implies that tissue organization, cell adhesion, and the ECM may synergistically generate apoptosis resistance in metastatic tumors. We showed previously that ECM-induced tissue architecture can override the proliferative and invasive malignant phenotype, but that reversion is dependent upon the 3D tissue microenvironment (Weaver et al., 1997; Wang et al., 1998). Because reversion of the malignant phenotype and polarity are associated with recalcitrance to growth factor stimulation, we have now hypothesized that the ECM, via cooperative interactions between integrins, the cytoskeleton, and 3D tissue organization, dictates apoptosis inducibility in mammary epithelial cells (MECs).

To show this, we used the HMT-3522 MEC model of breast cancer progression (Briand et al., 1996; Weaver et al., 1996). This tumor cell series was established from a reduction mammaplasty of a woman with a nonmalignant breast lesion. Continued passage and growth factor withdrawal led to the spontaneous generation of tumorigenic cells (Briand et al., 1996). We used the nonmalignant S-1 cells at passages 50–70 ("normal"; S-1) and their tumorigenic progeny at passages 238–245 (T4-2). In the present study we asked whether BM signaling via integrins regulates apoptosis resistance in 3D structures of MECs, and if so, how. We determined that the BM component laminin can drive resistance to apoptosis induced by immune modulators and cytotoxic drugs by driving polarization via $\alpha 6 \beta 4$ integrin-cytoskeletal interactions and NF κ B activation. Our data illustrate how the tissue microenvironment could rapidly influence the

emergence of multidrug-resistant tumors by influencing cell death regulators through effects on cell adhesion-directed tissue architecture.

Results

Studies using cells in two-dimensional (2D) monolayers have demonstrated clearly that deregulated expression of apoptosis-mediating or -inhibiting molecules can confer resistances to cytotoxic drugs and death receptor ligands (Kaufmann and Earnshaw, 2000; Zhang et al., 2000). Clinical studies in patients, however, often have failed to verify these observations. In contrast, excellent correlation is observed between resistances to drugs in three-dimensional (3D) cultures of primary cancer cells and immortalized malignant cells and tumors in vivo (Desoize and Jardiillier, 2000). Because we have observed previously that cells in 2D and 3D contexts integrate signaling pathways differently (Wang et al., 1998; Bissell et al., 1999; Bissell and Radisky, 2001), we asked whether 3D tissue architecture could alter apoptotic resistance to drugs, and if so, how? We therefore designed experiments to investigate the link between cell adhesion and 3D tissue architecture and the genesis of the apoptosis-resistant tumor phenotype.

A differentiated tissue structure is resistant to apoptosis induction

We asked whether interactions with BM modulate the sensitivity of MECs to apoptotic stimuli in 3D cultures, and if malignant transformation altered this responsiveness. We measured the apoptotic sensitivity of S-1 and malignant T4-2 MECs to apoptotic stimuli in 2D and 3D. S-1 and T4-2 MECs, grown as 2D monolayers on a thin coat of collagen I, exhibited comparable apoptotic responsiveness regardless of the kind of apoptotic agent used. These included ligation of receptors for tumor ne-

crosis factor (TNF- α), Trail, Fas, or treatment with the microtubule reagent paclitaxol, the topoisomerase II inhibitor etoposide, or the actin cytoskeletal disruptor cytochalasin B (Figure 1).

Nonmalignant MECs embedded in reconstituted BM (rBM) formed growth-arrested 3D organoids (acini), whereas malignant MECs continued to proliferate to form nonpolar, multicellular, and disorganized 3D aggregates (Petersen et al., 1992; Weaver et al., 1997). The rBM conferred apoptosis resistance

to nonmalignant MEC acini; however, this mechanism was absent or was no longer functioning after malignant transformation (Figure 1B).

A polarized mammary tissue structure is resistant to apoptosis induction

To determine whether the differential sensitivity in nonmalignant and malignant cells in 3D was a direct function of genetic

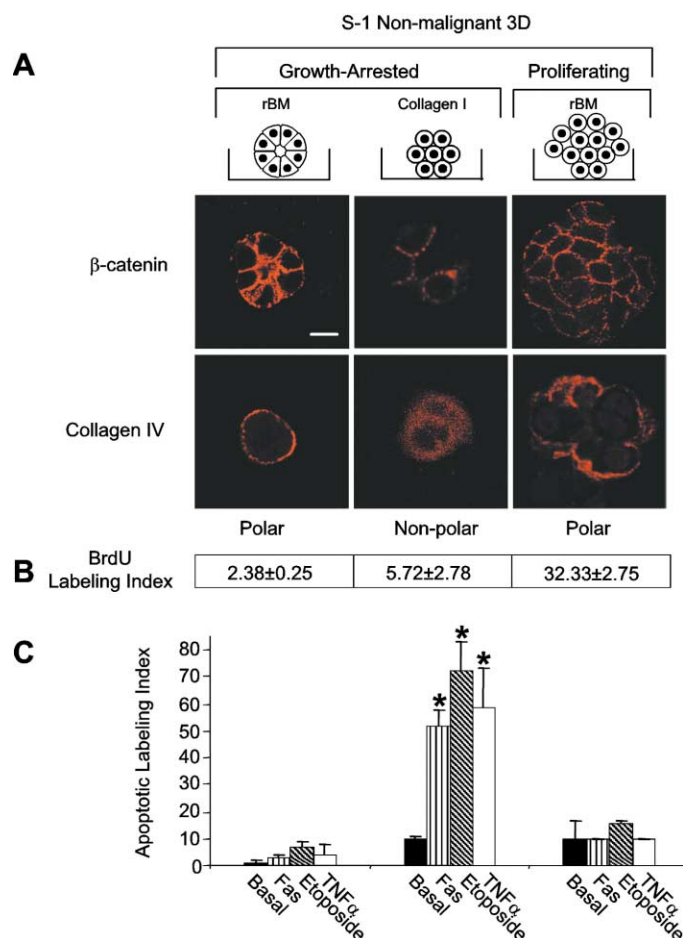

Figure 3. The polarized acini resist apoptosis induction regardless of growth status

A: Confocal microscopy of β-catenin and collagen IV. Control S-1 structures in rBM, S-1 in collagen I gels, and S-1 cells overexpressing EGF-R in rBM show β-catenin (Texas red) localized at cell-cell (adherens) junctions. However, only the structures generated in the rBM acquired basal polarity as marked by the basal deposition of collagen IV (Texas red). All cultures were analyzed after 10 days in 3D gels. **B:** BrdU labeling indices for S-1 cells incorporated into 3D structures as described in **A**. Results are mean ± SEM of three separate experiments of 200–400 cells per experiment. **C:** S-1 cells propagated as described in **A** were induced to undergo apoptosis by TNF-α (100 nM), etoposide (50 μM), or anti-FAS mAb (2 μg/ml) for 96 hr. Results are mean ± SEM of 3–5 separate experiments, each with duplicates or triplicates. Bar equals 10 μm.

changes or whether it was the indirect result of the inability of the T4-2 cells to form organized structures, we induced them to form polarized “reverted” structures (T4-Rvt), as described previously, by growing them within the rBM in the presence of a function-blocking β1 integrin monoclonal antibody (mAb) (Weaver et al., 1997). T4-2 cells grown with the irrelevant antibody served as apoptosis-sensitive controls. Both S-1 acini and T4-Rvt structures established tissue polarity as shown by cortical actin, β-catenin at cell-cell junctions, and secreted laminin-5 and β4 integrin at their basal surface (Figure 2A) and were resistant to apoptosis by all three apoptotic agents tested (Figure 2B). Conversely, disruption of polarity by treating S-1 cells with a function-blocking anti-E-cadherin mAb (Figure 2A; Day et al., 1999) inside the rBM resulted in clusters of cells

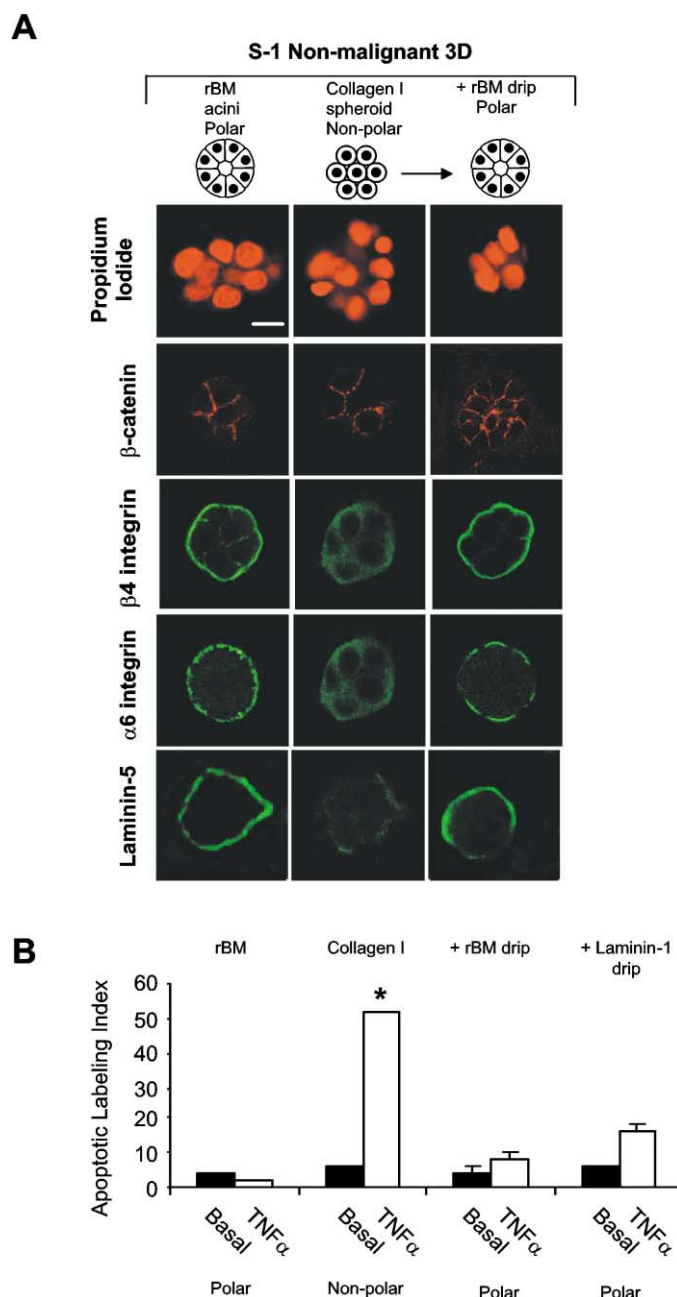

Figure 4. BM-induced tissue polarity is necessary for apoptosis resistance

S-1 cells were grown either inside the rBM, inside collagen I, or inside collagen I followed by addition of either rBM or laminin-1. **A:** Confocal microscopy of Z sections of nuclei (propidium iodide), β-catenin (Texas red), β4 integrin (FITC), α6 integrin (FITC), and laminin-5 (FITC) fluorescence. All structures had β-catenin localized at cell-cell junctions. Although 3D structures grown in contact with collagen I had cytosolic β4 and α6 integrins and dispersed laminin-5, when these cells were overlaid with rBM or laminin-1 (not shown), their β4 and α6 integrins became reorganized to the site of cell-rBM interactions, and they assembled an endogenous BM as shown by deposition of laminin-5 at the cell-rBM junction. **B:** Apoptotic labeling indices calculated for S-1 cells grown as described in **A**. Cultures were treated with TNF-α (100 μM) for 96 hr. Results are mean ± SEM of 3–6 separate experiments, each with duplicates or triplicates. Bar equals 10 μm.

with disordered filamentous actin, dispersed $\beta 4$ integrin, and intracellular and randomly secreted laminin-5, similar to the disorganized T4-2 colonies (Figure 2A). The disorganized S1 cells now became very sensitive when the acinar polarity was compromised (Figure 2B).

BM-induced tissue polarity is necessary for apoptosis resistance regardless of growth status

Cytotoxic drugs induce apoptosis in target cells based upon their capacity to promote cell-cycle arrest (Roninson et al., 2001; Hurley, 2002). Because the formation of tissue polarity and apoptosis resistance was also associated with a substantial reduction in cell growth (Figure 2C), we asked whether growth arrest was sufficient for apoptosis resistance. S1 cells form polarized, growth-arrested structures within 3D rBM, whereas they growth arrest within 3D collagen I gels but are not polarized (Lelievre et al., 1998; Gudjonsson et al., 2002). In addition, S-1 cells that overexpress EGF-R (Wang et al., 1998) continue to proliferate but maintain basal polarity within rBM (Figure 3A). All three groups maintain adherens junctions as shown by β -catenin localized at cell-cell junctions (Figure 3A). A comparison of apoptotic response indicated that only those MECs that were basally polarized, as indicated by deposition of an endogenous BM (Figure 3A), were resistant to apoptosis following treatment with TNF- α , Fas mAb, or etoposide, whether growth-arrested or proliferating (Figures 3B and 3C). In contrast, growth-arrested but nonpolarized S-1 cells underwent apoptosis.

To investigate whether it is the presence of rBM molecules per se or whether rBM-induced polarity is required for protection, we grew S-1 cells as 3D nonpolar spheroids within collagen I gels or as 3D polar acini in rBM. In parallel, we liberated some MEC 3D spheroids by collagenase treatment, suspended them in polyHEMA-coated dishes, and then overlaid them with serum-free medium supplemented with either BSA or rBM proteins. All of these tissue structures were growth arrested (see Figure 3B) and showed adherens junctions as assessed by β -catenin (Figure 4A). Apoptosis could be readily induced in the S-1 nonpolar spheroids in collagen I gels, but once exposed to rBM, they resembled polarized S-1 acini with basally localized $\beta 4$ and $\alpha 6$ integrins and laminin-5, and they acquired apoptosis resistance (Figure 4B).

Addition of laminin-1, the main component of the rBM, to 3D collagen gels was shown previously to restore polarity to luminal breast epithelial cells (Gudjonsson et al., 2002). Laminin-1 was also sufficient for inhibiting apoptosis sensitivity in our experiments (Figure 4B). These results demonstrate that tissue polarity, resulting from interaction with BM laminins, but not other ECM molecules such as collagen I, is necessary and sufficient for protection from apoptosis induction.

BM-induced tissue polarity regulates NF κ B activation to drive apoptosis resistance

NF κ B is activated early during neoplastic transformation of the mammary gland in rodents (Kim et al., 2000) and may play an important role also in the pathogenesis (Sovak et al., 1997) and metastasis of human breast cancers (Nakshatri et al., 1997). Activated NF κ B is linked to repression of apoptosis during mammary involution in mice and increased survival of murine mammary epithelial cells in culture (Clarkson et al., 2000). NF κ B activation also drives resistance to chemo- and radiation therapy (Baldwin, 2001; Baeuerle and Baltimore, 1996) and modifies

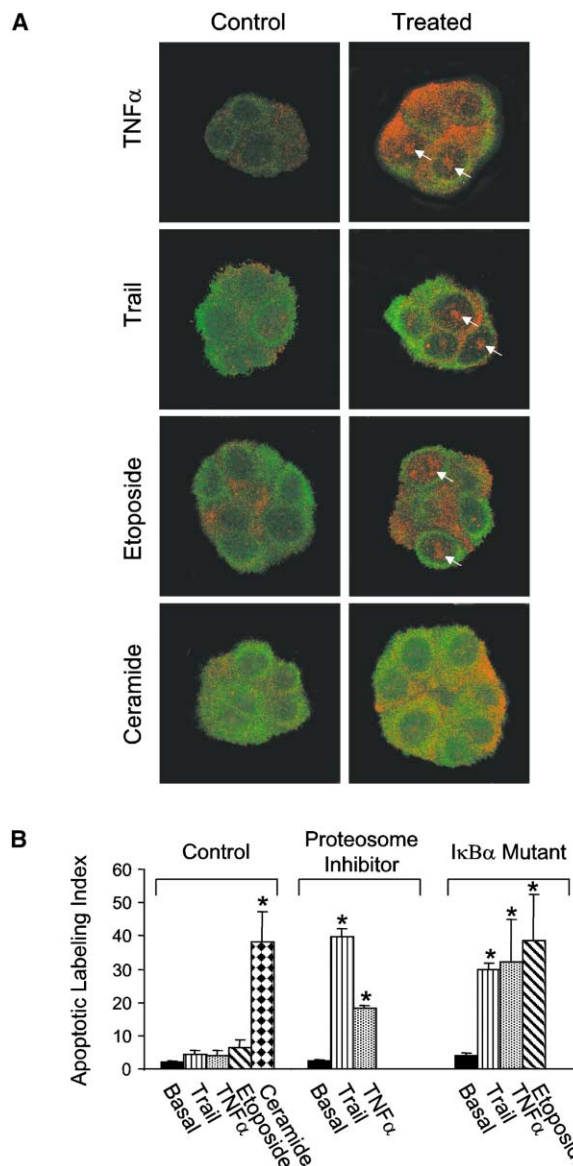

Figure 5. BM-induced tissue polarity regulates NF κ B activation and drives apoptosis resistance in acini

A: Confocal microscopy of cytochrome 18 and NF κ B p65. Control S-1 acini in rBM treated for 1 hr with TNF- α (100 nM), Trail peptide (1 μ g/ml), or etoposide (50 μ M) show cytoplasmic (cytochrome 18; FITC) to nuclear translocation of NF κ B p65 (Texas red), whereas acini treated with C2-ceramide (5 μ M) do not. **B:** Cell viability calculated for control S-1 cells or S-1 cells expressing a proteolytically resistant mutant I κ B α grown in rBM to form acini and then treated as described in **A** in the presence or absence of the multicatalytic proteasome inhibitor MG 132 (5 μ M). Results are mean \pm SEM of 3–4 separate experiments with 200–600 cells scored in each.

expression and stability of apoptosis regulators (Tanaka et al., 2000; Tergaonkar et al., 2002). Accordingly, we investigated the relationship of NF κ B p65 activation to BM-induced polarity and apoptosis resistance. Within 1 hr of treatment of polarized S-1 acini with TNF- α , Trail, or etoposide, nuclear localization of NF κ B B p65 increased measurably (Figure 5A). When we used the multicatalytic proteasome inhibitor MG 132 or expressed a mutant I κ B α , which is resistant to proteolytic degradation, nuclear translocation of p65 did not occur (data not shown) and all

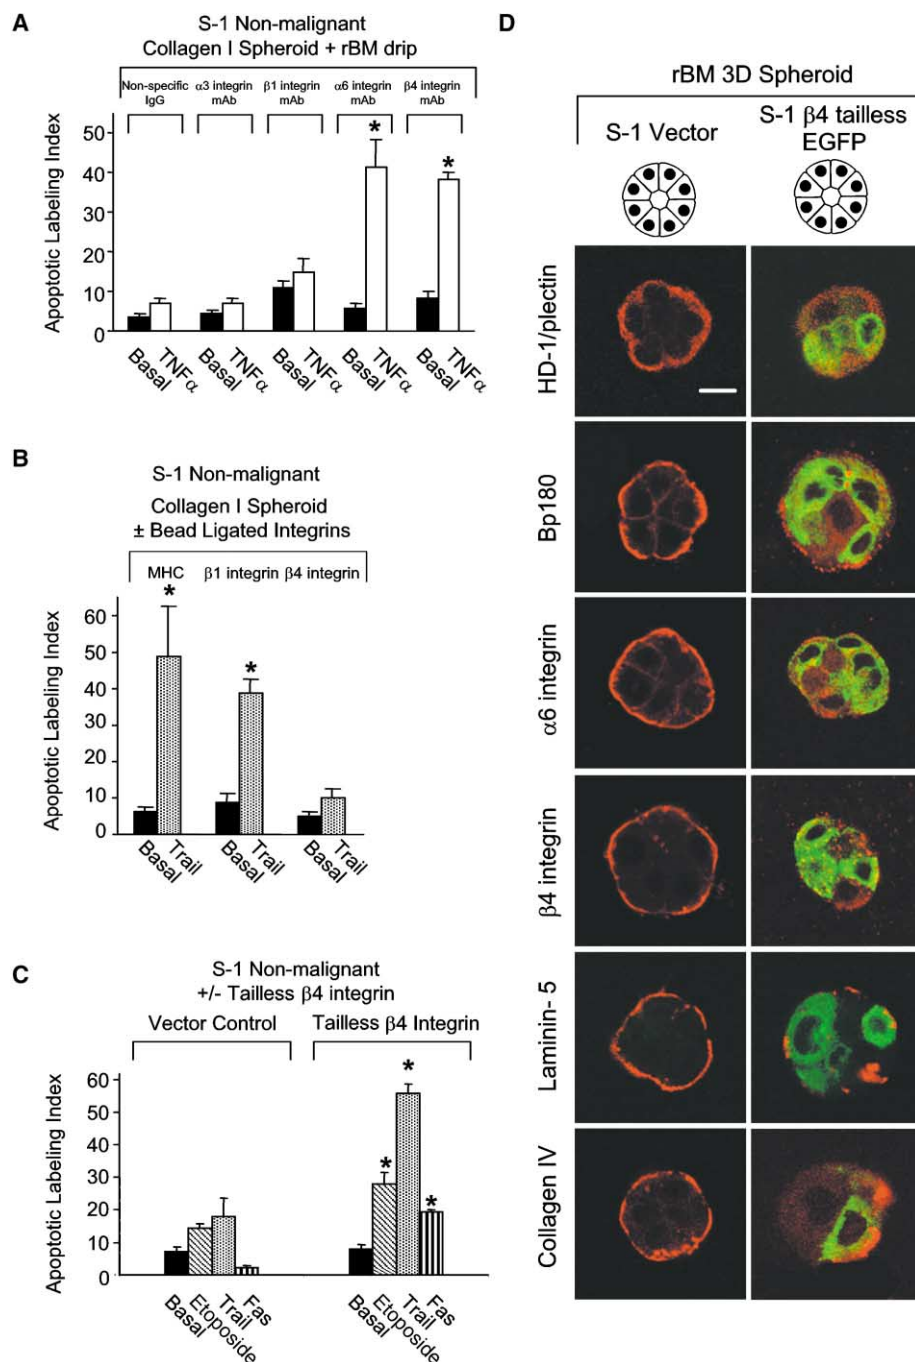

Figure 6. $\alpha 6 \beta 4$ integrin directs apoptosis resistance in 3D mammary organoids

A: Apoptotic labeling indices calculated for S-1 cells grown in collagen I and preincubated with function-blocking mAb against $\alpha 3$ integrin (clone P15B), $\beta 1$ integrin (clone A1B2), $\alpha 6$ integrin (clone GoH3), $\beta 4$ integrin (clone ASC 3), or an isotype-specific IgG control for 30 min, overlaid with rBM and then treated in suspension culture with TNF- α (100 μ M) for 96 hr. Results are the mean \pm SEM of 4–8 separate experiments, all in triplicate. **B:** Apoptotic labeling indices calculated for S-1 cells grown in collagen I gels following ligation and clustering of $\beta 1$ or $\beta 4$ integrin or a MHC cell surface molecule for 1 hr and then treated with Trail (1 μ g/ml) for 96 hr. Results are the mean \pm SEM of 2–6 separate experiments, each with duplicates. **C:** Apoptotic labeling indices calculated for S-1 vector or tailless $\beta 4$ integrin-expressing cells grown in rBM for 10 days and treatment with etoposide (50 μ M), Fas mAb (1 μ g/ml), or Trail (1 μ g/ml) for 96 hr. Results are the mean \pm SEM of three separate experiments. **D:** Immunofluorescence of HD-1, BP180, $\alpha 6$ integrin, $\beta 4$ integrin, collagen IV, and laminin-5 (Texas red) in S-1 control versus S-1 expressing tailless $\beta 4$ integrin (GFP). Bar equals 10 μ M.

three of these agents induced apoptosis (Figure 5B). In contrast, ceramide, which fails to induce nuclear translocation of NF κ B, induced death in S-1 acini under all conditions (Figures 5A and 5B). These data show that BM-induced polarity modulates endogenous NF κ B activation in epithelial acini and is one mechanism mediating BM-induced apoptosis resistance in MEC acini.

$\alpha 6 \beta 4$ integrin directs apoptosis resistance in 3D mammary organoids

To address which laminin receptor is necessary for induction of polarity and apoptosis resistance, we incubated nonpolar,

apoptosis-sensitive S-1 spheroids isolated from collagen I gels with function-blocking mAb to $\alpha 2$, $\alpha 3$, $\alpha 6$, $\beta 1$, or $\beta 4$ integrin or control IgG. The structures were suspended in polyHEMA-coated dishes in serum-free media supplemented with either BSA or rBM. The spheroids treated with rBM, but not BSA, that were challenged with TNF- α in the presence of mAb directed against $\beta 1$, $\alpha 2$, or $\alpha 3$ integrins were viable and intact, even after 96 hr of incubation (Figure 6A), and showed nuclear translocation of NF κ B (data not shown). In contrast, cells in the rBM-treated spheroids incubated with blocking mAbs to $\alpha 6$ or $\beta 4$ integrins failed to establish polarity, did not activate NF κ B (data

not shown), and showed significantly increased apoptosis when challenged with TNF- α for 96 hr (Figure 6A). Because S-1 MECs do not express $\alpha 6 \beta 1$ integrin (data not shown), these results indicate that $\alpha 6 \beta 4$ integrins, but not $\alpha 2 \beta 1$ or $\alpha 3 \beta 1$ integrins, participate in regulating BM-directed apoptosis resistance in polarized acini.

To establish whether ligation of $\beta 4$ integrins was sufficient to protect the nonpolarized spheroids from apoptosis induction, we ligated and clustered their $\beta 1$ or $\beta 4$ integrins or MHC molecules with mAbs that were crosslinked to magnetic beads. The integrin-activated 3D MEC structures were suspended in poly-HEMA-coated dishes in serum-free medium. mAb-bead-mediated ligation of $\beta 4$, but not $\beta 1$ integrins, protected the MEC spheroids from apoptosis induction (Figure 6B). Conversely, when S-1 cells expressing a GFP-labeled tailless $\beta 4$ integrin were embedded in rBM to form growth-arrested structures, NF κ B did not translocate to the nucleus following drug treatment (data not shown) and cells did not develop polarity (Figure 6D). These structures showed disrupted hemidesmosome formation, as indicated by randomly dispersed type 1 hemidesmosome protein, HD-1, and bullous pemphigoid antigen 180 (BP180; Figure 6D). Loss of tissue polarity and NF κ B activation in these growth-arrested structures was associated with enhanced sensitivity to apoptosis induced by etoposide, Trail, and Fas receptor ligation (Figure 6C). Thus, the ability of $\beta 4$ integrins to drive tissue polarity is essential for activation of NF κ B and apoptosis resistance.

Disrupting hemidesmosome formation perturbs BM-directed tissue polarity, inhibits NF κ B activation, and permits induction of apoptosis in 3D acini

An important function of $\beta 4$ integrin is to functionally link the cytoskeleton to hemidesmosomes. Accordingly, we investigated the role played by hemidesmosomes in induction of polarity, NF κ B activation, and apoptosis resistance in MEC acini. T4-2 nonpolar spheroids in rBM had sparsely dispersed hemidesmosomes (1 hemidesmosome/2 μ m plasma membrane), of which >90% were immature type II hemidesmosomes, disorganized $\beta 4$ integrin, a sparse random distribution of HD-1, and predominantly cytosolic NF κ B p65 (Figure 7). In contrast, T4-2 cells in rBM, treated with a function-blocking $\beta 1$ integrin mAb but not nonspecific rat IgGs, reverted to polarized acini (Figure 7; see also Figure 2A). The polarized, reverted T4 structures had basally organized $\beta 4$ integrin and HD-1, increased hemidesmosomes (2 hemidesmosomes/3 μ m plasma membrane) of which >60% were mature type I hemidesmosomes and nuclear localization of NF κ B p65 (Figure 7). These observations establish an association between $\beta 4$ integrin-directed tissue polarity, hemidesmosomes, and BM-induced apoptosis resistance.

Several amino acid residues in the connecting segment that resides between the four type-III fibronectin-like modules, toward the C terminus, are critical for targeting $\beta 4$ integrin to hemidesmosomes (Figure 8A). To test the involvement of hemidesmosomes, S-1 cells were transfected with one of the following: an untagged or RFP- or EGFP-tagged $\beta 4$ integrin deleted in the cytoplasmic tail connecting segment ($\Delta 1314$ -1486), or wild-type $\beta 4$ integrin, or vector control RFP- or EGFP-tagged or untagged constructs. Pooled stable populations of S-1 cells transfected with the connecting segment deleted $\beta 4$ or wild-type $\beta 4$ integrin showed uniform expression of tagged RFP protein (Figure 8C) and increased total $\beta 4$ integrin expression

Figure 7. Apoptosis resistance in reverted tumor cells is associated with increased levels of mature hemidesmosomes and constitutive activation of NF κ B

T4-2 cells were grown inside rBM with control mAb or were reverted with $\beta 1$ integrin inhibitory mAb (A1B2) and were analyzed after 12 days by transmission electron microscopy (TEM) and immunofluorescence. Both structures expressed the hemidesmosome proteins $\beta 4$ integrin and HD-1 and contained hemidesmosomes; note, however, they are less abundant in the T4-2 control spheroids (1/2 μ m plasma membrane), and of these, 90% are immature type II structures. Hemidesmosomes are more abundant in the T4-revertants (Rvts), and 60% are of mature type I and are assembled at the basal tissue domain where $\beta 4$ integrin and HD-1 are located. Hemidesmosome formation in the T4-Rvts is associated with constitutively localized NF κ B p65. Bars equal TEM 50 nm; confocal 10 μ M.

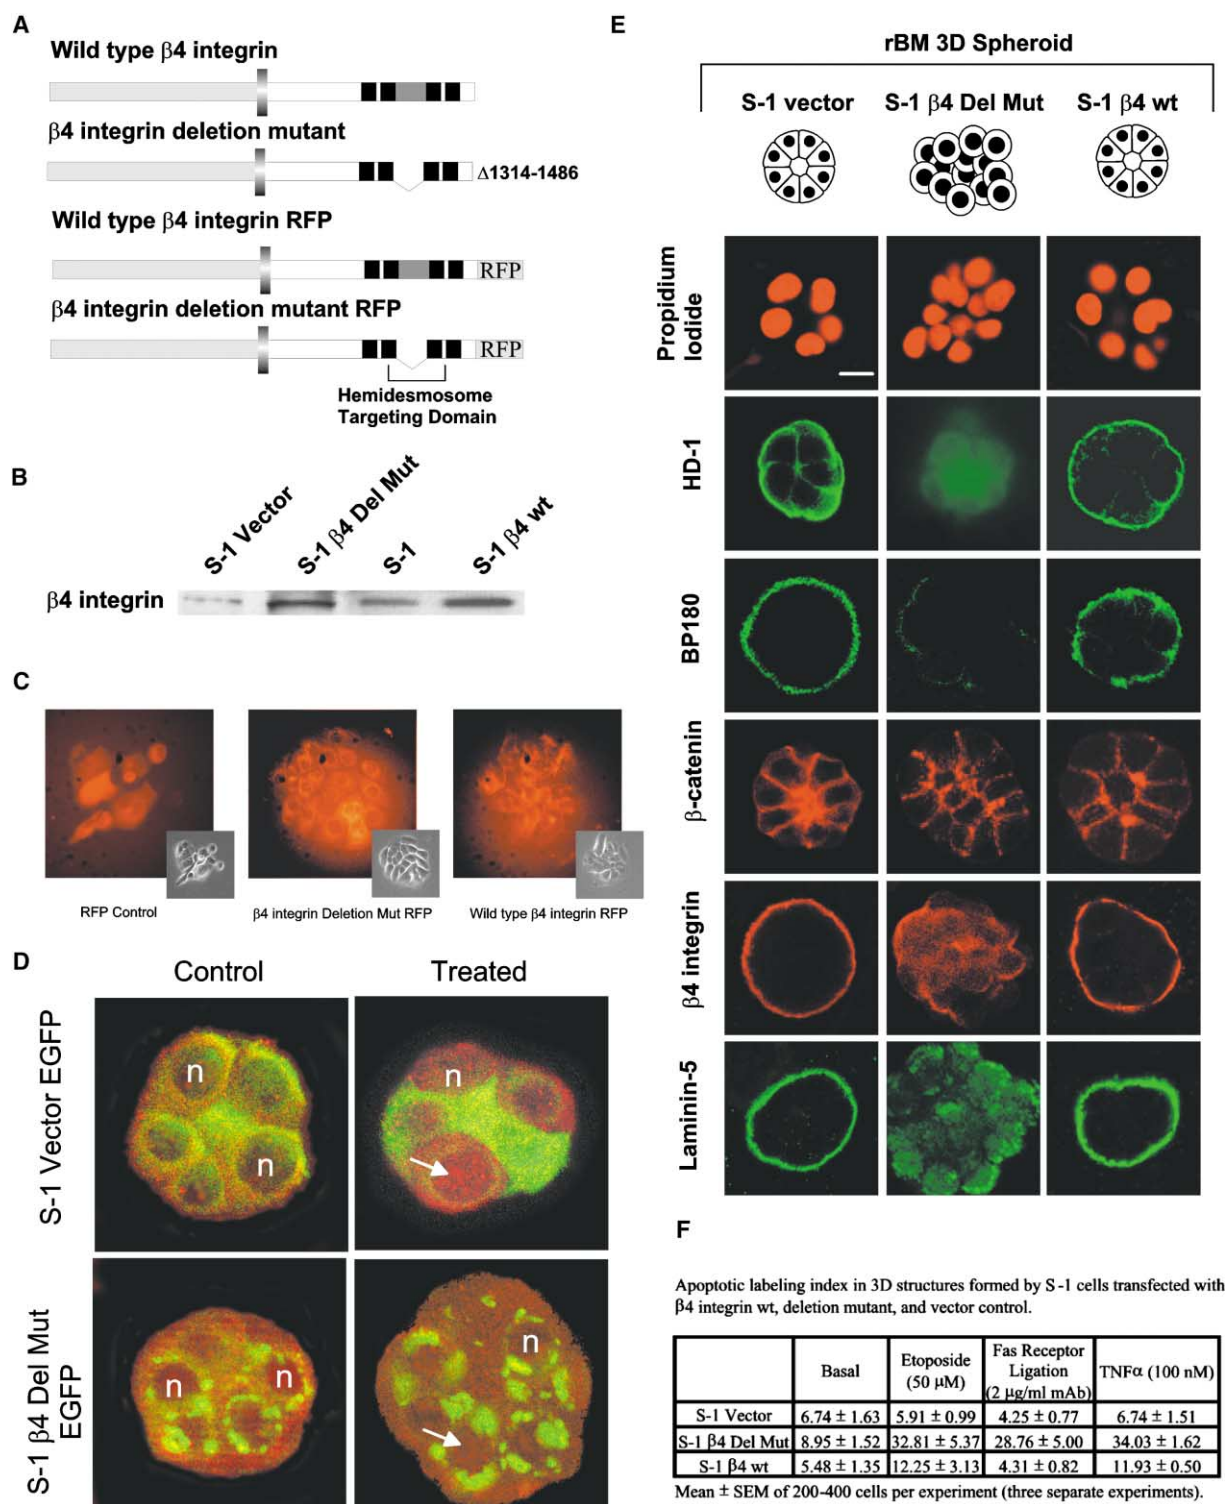

Figure 8. Disrupting hemidesmosome formation perturbs BM-directed tissue polarity, inhibits NF κ B activation, and permits induction of apoptosis in 3D acini

A: Diagram of $\beta 4$ integrin showing the hemidesmosome targeting domain in the cytoplasmic tail of the $\beta 4$ integrin protein and the RFP tag. **B:** Western blot of RIPA lysates of S-1 cells showing that the deleted and wild-type $\beta 4$ integrin transfectants expressed elevated total levels of $\beta 4$ integrin protein relative to the vector controls. **C:** Phase contrast and immunofluorescence of $\beta 4$ integrin deleted, wild-type, and vector control RFP-expressing S-1 cells in 2D. **D:** Immunofluorescence of NF κ B p65 (Texas red) in S-1 cells in rBM expressing EGFP-tagged mutant $\beta 4$ integrin and EGFP vector controls before and after 1 hr of TNF- α treatment (100 μ M) showing reduced cytoplasmic to nuclear translocation of NF κ B p65 in mutant $\beta 4$ integrin expressing S-1 cells. **E:** Immunofluorescence of HD-1 (FITC), BP180 (FITC), β -catenin (Texas red), $\beta 4$ integrin (Texas red), and laminin-5 (FITC) fluorescence in S-1 cells in rBM expressing mutant and wild-type $\beta 4$ integrins and vector controls. 3D cultures were analyzed after 12 days inside rBM. Bar equals 10 μ m. **F:** Apoptotic labeling indices calculated after 12 days cultivation in the rBM and treatment for 96 hr with TNF- α (100 μ M), FAS receptor mAb (2 μ g/ml), or etoposide (50 μ M). Results are the mean \pm SEM of three separate experiments.

compared to S-1 vector controls (Figure 8B). All cells in 3D rBM assembled adherens junctions judged by localization of β -catenin (Figure 8E). Expression of the $\beta 4$ integrin with the connecting segment deleted should act as a dominant negative by competing with the endogenous, wild-type $\beta 4$ integrin to disturb hemidesmosome organization and perturb cytoskeletal organization. S-1 cells transfected with mutant $\beta 4$ integrin consistently formed structures with dispersed, faint HD-1; with patchy, sparsely distributed BP180; with cytosolic, nonpolarized $\beta 4$ integrin; and with randomly secreted laminin-5, indicating that disrupting hemidesmosome-cytoskeletal structures perturbed polarity (Figure 8E). In contrast, vector control or S-1 cells infected with wild-type $\beta 4$ integrin were polarized with intense staining for HD-1 protein and punctate basal BP180 (Figure 8E). Moreover, perturbing hemidesmosome organization in the 3D MEC structures with mutant EGFP-tagged $\beta 4$ integrin reduced NF κ B activation and led to a significant enhancement in apoptosis sensitivity (Figures 8D and 8F). These observations establish that ligation of $\alpha 6\beta 4$ integrins, formation of mature hemidesmosomes, and activation of NF κ B p65 are linked to BM-directed tissue polarity and resistance to apoptosis.

Discussion

These studies emphasize the important contribution of the tissue microenvironment and tissue architecture both in the mediation of normal breast tissue viability as well as in the generation of the apoptosis-resistant phenotype of breast tumors. Our data stress the relevance of recapitulating cellular context when attempting to delineate the mechanisms underlying cell behavior. By taking advantage of the mammary epithelial tumor progression model, HMT-3522, and 3D assays in rBM or collagen-I gels, we were able to determine how nonmalignant and tumorigenic breast epithelial cells could become resistant to apoptosis. The studies described here show that tissue architecture regulates sensitivity to exogenous apoptotic stimuli and that this effect is mediated via integrin-cytoskeletal associations and activation of NF κ B. Laminin-induced ligation of $\beta 4$ integrin directs tissue polarity and promotes resistance to apoptosis in both nonmalignant and malignant breast epithelial structures, regardless of growth status. The apoptosis resistance depends upon the 3D organization of the acini and is functionally linked to $\beta 4$ integrin-directed hemidesmosome formation and NF κ B activation. Thus, integrin-laminin interactions not only initiate signals essential for cell growth, viability, and functional differentiation (Streuli et al., 1991; Boudreau et al., 1995; Howlett et al., 1995), but also protect mammary cells that are organized into tissue-like structures from exogenous apoptotic cues. The unit structure of the tissue thus emerges as an important determinant of normal tissue homeostasis (Bissell et al., 1999).

The presence of hemidesmosomes in epithelial tissues stabilizes attachments to the underlying BM (Jones et al., 1998). $\alpha 6\beta 4$ integrins play a diverse role in normal epithelial physiology (Borradori and Sonnenberg, 1999) by acting as laminin receptors that interact with intermediate filaments via long cytoplasmic tails (Spinardi et al., 1995). This facilitates branching morphogenesis (Stahl et al., 1997), cell proliferation (Mainiero et al., 1997), and migration (Goldfinger et al., 1999). Here we show that ligand-activated $\beta 4$ integrin is involved directly in induction of tissue polarity in mammary epithelial acini and in modulating a program that leads to the acquisition of apoptosis resistance

to most receptor-linked and many chemical stimuli. This phenotype requires $\beta 4$ integrin to mediate hemidesmosome formation and to facilitate NF κ B activation. In support of these results, $\beta 4$ integrin null keratinocytes exhibit reduced viability in response to an exogenous mechanical stress in vivo (Dowling et al., 1996), and targeted disruption of the *LAMA3* gene in mice compromises keratinocyte survival (Ryan et al., 1999). Similarly, $\beta 1$ and $\beta 4$ integrins activate NF κ B to maintain survival during T cell development (Fiorini et al., 2000; Scupoli et al., 2000).

But how do tumor cells evade apoptotic therapy and what is the link to polarity? Our data suggest that epithelial tumors that express $\beta 4$ integrins have the potential to acquire resistance to exogenous death stimuli if they are given the appropriate spatial and biochemical cues from the microenvironment. The T4-2 breast tumor cells express $\beta 4$ integrin and are sensitive to induction of apoptosis when they are grown in both two-dimensional and three-dimensional cultures. However, they acquire an apoptosis-resistant phenotype when they recapitulate a three-dimensional, polarized architecture accompanied with endogenously activated NF κ B p65. These findings provide a rationale for a number of previous reports in the literature. Aggressive and metastatic breast tumor cell lines express $\beta 4$ integrins (Taylor-Papadimitriou et al., 1993; Jones et al., 1997). Furthermore, the highly metastatic, $\alpha 6\beta 4$ integrin-positive breast epithelial cell line MDA MB-231 rapidly and reversibly acquires a multidrug apoptosis-resistant phenotype when grown in three dimensions (Graham et al., 1994; Kerbel et al., 1996; St. Croix et al., 1998). The data are also consistent with clinical reports that individuals expressing both BM proteins and $\beta 4$ integrins in their primary tumors have the poorest prognosis among breast cancer patients (Tagliabue et al., 1998) and that breast tumors frequently show increased expression of NF κ B-regulated genes such as survivin (Tanaka et al., 2000). A recent study showed that more than 60% of primary breast tumor tissues express high levels of both $\beta 4$ integrin and laminin-5 (Davis et al., 2001) and more than 50% of dormant, metastatic cells isolated from the bone marrow of breast cancer patients express $\alpha 6$ and/or $\beta 4$ integrins (Putz et al., 1999). Furthermore, deregulated NF κ B has been implicated as an important prognostic indicator in primary and metastatic breast tumors (Nakshatri et al., 1997; Sovak et al., 1997; Kim et al., 2000), underscoring the potential relevance of our present studies to tumor pathology.

Our model suggests that integrin-directed tumor architecture may constitute a prognostic indicator of future tumor behavior and apoptosis sensitivity. The major event regulating tumor metastasis is survival of the tumor cell in the distant site (Wong et al., 2001). Accordingly, our data may explain why tumors preferentially colonize selected tissues. In addition to providing the soluble factors and blood flow dynamics deemed necessary for promoting the dissemination of metastatic tumor cells (Taylor et al., 2000), viable sites for tumor metastasis may also provide the appropriate ECM, microenvironmental, and spatial information critical for tumor cell survival.

Experimental procedures

Substrates and antibodies

The material used were as follows: commercial EHS matrix (Matrigel™, Collaborative Research) for the rBM assays; Vitrogen (Vitrogen 100, Celtrix Laboratories; bovine skin collagen I), 3 mg/ml, for coating culture dishes; Cellagen Solution AC-5, 0.5% (ICN Biomedical, Inc.) for the 3D collagen I assays; and poly HEMA, 6 mg/ml (Sigma Chemicals) for the cell suspension

studies. Antibodies used were: collagen IV, clone PHM-12 (Biogenex); laminin-5 $\alpha 3$ chain specific, clone BM165 (gift of M.P. Marinkovich, Stanford; Rousselle et al., 1991); $\alpha 6$ integrin, clones J15B (gift of C. Damsky, UCSF) and GoH3 (Chemicon International); $\alpha 2$ integrin, clone 10G11, and $\alpha 3$ integrin, clone P15B (Chemicon International); $\beta 1$ integrin, clones AIB2 (gift of C. Damsky, UCSF) and TS2-16 (gift of M. Hemler, Harvard); $\beta 4$ integrin, rabbit sera, and clones 3E1, ASC-3, and ASC-8 (Chemicon International); BP180, rabbit sera J17 (J. Jones, Northwestern); HD-1, clone 121 (gift of K. Owaribe, Graduate School of Human Informatics, Okazaki, Japan; Okumura et al., 1999); β -catenin, clone 14 (Transduction Laboratories); FAS receptor, clones IgM CH-11 (MBL Co., Ltd.) and CD95 (Immunotech, Inc.); E-cadherin clone HECD-1 (Zymed); NF κ B p65, rabbit sera (Santa Cruz); cytokeratin 18, clone RCK106 (Transduction Laboratories); human MHC class I clone W6.32 (Sigma); and actin, FITC-conjugated Phalloidin (Molecular Probes), fluorescein- and Texas red-conjugated, nonconjugated anti-mouse and anti-rat, and nonspecific rat and mouse IgGs (Jackson Laboratories). The multicatalytic proteasome inhibitor MG132 (5 mM stock in DMSO; Calbiochem) was used at 0.5–5.0 μ M.

Cell culture

The HMT-3522 MECs were grown and manipulated in 2D and 3D as described (Petersen et al., 1992; Weaver et al., 1997). Phenotypic reversion of T4-2 cells, using $\beta 1$ integrin function-blocking mAb, and disruption of S-1 morphogenesis, using the E-cadherin function-blocking mAb, were exactly as described (Weaver et al., 1997; Wang et al., 1998).

Indirect immunofluorescence analysis and image acquisition

Cells were either directly fixed using 2% paraformaldehyde or in 1:1 methanol:acetone or 100% methanol, or first extracted in situ using CSK buffer (50 mM HEPES, 300 mM sucrose, 100 mM KCl, 5 mM MgCl₂, 5 mM EDTA, 0.5% Triton X-100, containing 10 μ g/ml leupeptin, 10 μ g/ml pepstatin, 1 mM Pefabloc [Boehringer Mannheim], 10 μ g/ml E64, 25 μ g/ml aprotinin, 0.5 mM benzamide, 1 mM sodium orthovanadate, and 20 mM sodium fluoride) and subsequently fixed. In some experiments, cultures were embedded in sucrose and frozen in Tissue-Tek OCT compound (Miles Laboratories), and 5 μ m frozen sections were prepared for immunostaining. Cell samples were incubated with primary mAbs followed directly by either FITC- or Texas red-conjugated secondary Abs. Nuclei were counterstained with diamidinophenylindole (DAPI, Sigma) or propidium iodide (Sigma). Cells were visualized using a Bio-Rad MRC 1024 laser scanning confocal microscope attached to a Nikon Diaphot 200 microscope. All immunofluorescence images were recorded at 120 \times magnification.

Analysis of cell growth

The proliferation rate of cells was measured by assaying BrdU incorporation using a commercially available labeling and detection kit (Boehringer Mannheim). The BrdU-labeling index was determined by scoring the BrdU-positive cells and expressing this as a percentage of total cell number, estimated by counting the number of nuclei visualized by DAPI staining (200–400 cells).

Induction and analysis of apoptosis

Apoptosis was initiated by direct receptor trimerization using the FAS receptor antibody IgM Ch-11 (1–2 μ g/ml); by receptor ligation with CD95 (1–2 μ g/ml) followed by secondary mAb-induced clustering; and by treatment with recombinant, purified Trail (Apo2L, 1–4 μ g/ml; BioMol Research Laboratories Inc.), recombinant TNF- α (10–100 nM; R&D Systems Inc.), the topoisomerase II inhibitor, etoposide (10–100 μ M in DMSO; TopoGen Inc.), the microtubule agent paclitaxel (20–120 nM; Sigma), the actin microfilament drug cytochalasin B (1–2 μ g/ml; Sigma), the membrane permeable N-acetylphosphoglyceric acid C2-ceramide (0.5–5 μ M; BioMol), or the membrane-permeable nonactive N-acetylphosphoglyceric acid C2-dihydroxyceramide (0.5–5 μ M; BioMol). Screening assays for apoptosis included Live/Dead Assay (Molecular Probes), active caspase 3 detection and cleavage of PARP by immunoblot analysis, and increased expression of annexin V in treated cells (Pharmingen). After initial screening, routine assay for apoptosis in intact fixed cells or cryosections used a commercially available in situ apoptosis kit (Boehringer Mannheim). The apoptotic labeling index was calculated as cells positive for FITC-labeled 3'-OH DNA ends as a percentage of the total number of cells scored (200–400 cells). In some experiments, cell death by apoptosis was confirmed by showing that DNA cleavage could

be inhibited by prior treatment with the caspase inhibitors YVAD-CHO or DEVD-CHO (1 μ M; BioMol Research Laboratories Inc.).

BM overlay assay and integrin inhibition studies

To assay for effects of rBM overlay on multicellular structures, cells were grown in collagen I gels to form spheroids, growth-arrested by removal of EGF for 24 hr, collagenase-liberated, and suspended in polyHEMA-coated dishes in H14 media supplemented with either BSA or rBM proteins (2 mg/ml). To inhibit integrin function, the 3D multicellular structures were preincubated with $\alpha 2$ integrin (4–16 μ g IgG/ml); $\alpha 3$ integrin (1:25–1:100 ascites/ml); $\alpha 6$ integrin (4–12 μ g IgG/ml); $\beta 1$ integrin (1:25–1:100 ascites/ml); $\beta 4$ integrin (4–16 μ g IgG/ml); or IgG isotype matched control mAb (4–16 μ g IgG/ml).

Antibody-conjugated beads and integrin activation studies

Monoclonal anti-human $\beta 1$ -integrin (TS2-16), $\beta 4$ -integrin (3E1), human MHC class I (W6.32), or nonspecific IgG control mAb was covalently attached to magnetic porous glass beads (5 μ m) by hydrazide crosslinking (CPG Inc.). Briefly, IgG protein was diluted (200 μ g/ml; 100 μ g total IgG), dialyzed overnight in oxidation buffer (100 mM sodium acetate, 150 mM sodium chloride [pH 5.5]), and then activated by periodate treatment (10 mM sodium periodate). After quenching (50% glycerol), mAb was dialyzed into coupling buffer (100 mM sodium acetate, 150 mM sodium chloride [pH 4.5]) and linked to prewashed MPG hydrazide beads, capped (67 mM glyceraldehyde, in coupling buffer), washed, and stored in buffer (PBS: 138 mM sodium chloride, 2.7 mM potassium chloride, 8.1 mM disodium phosphate, 1.2 mM potassium phosphate, 0.5 mM magnesium chloride, 0.1% Tween 20). To monitor for apoptosis resistance induced by integrin activation in 3D spheroids, prewashed (10 \times DMEM:F12) mAb crosslinked beads (1 μ g IgG/2 \times 10⁵ beads/10⁵ cells) were preincubated with suspensions of collagenase-liberated 3D collagen I structures followed by incubation with the apoptosis-inducing agent.

Electron microscopy analysis

Cells in rBM were fixed for a minimum of 30 min (2% glutaraldehyde in 0.1 M sodium cacodylate buffer [pH 7.2]), washed three times in 0.1 M sodium cacodylate buffer, postfixed (1% OsO₄ containing 0.8% potassium ferricyanide), stained with uranyl acetate, dehydrated in ethanol, and embedded in Epon-Araldite resin (Tousimis Corp.). Thin sections of embedded material were stained with lead nitrate and sodium citrate and viewed at 60 kV in a JEOL 100CX electron microscope (JEOL USA).

Preparation of MECs expressing mutant $\beta 4$ integrin and the $\text{I}\kappa\text{B}\alpha$ mutant

S-1 nonmalignant HMT-3522 cells were transfected with mutant $\beta 4$ integrin connecting segment deleted and pcDNA 3.1 plasmid DNA using LipofectAMINE (GIBCO-BRL) or infected with GFP-tagged tailless $\beta 4$ integrin or RFP-tagged connecting segment mutant or wild-type $\beta 4$ integrin, or mutant $\text{I}\kappa\text{B}\alpha$ (P. Khavari, Stanford; Seitz et al., 2000), or untagged wild-type or mutant $\beta 4$ integrin retroviral supernatant. Vector controls were prepared by transfecting with plasmid 3.1 pcDNA, or GFP, RFP, or empty retroviral vector. Resistant $\beta 4$ integrin or vector control cells were selected using G418 (plasmid) or blasticidin (retrovirus), whereas experiments conducted using the $\text{I}\kappa\text{B}\alpha$ mutant were done using nonselected pooled cell populations.

Flow cytometry

Cells grown as 2D monolayers were isolated, and nonspecific binding was blocked (60 min Dulbecco's PBS, 1% bovine serum albumin). They were then incubated with saturating concentrations of primary mAb and washed three times and labeled with fluorescein isothiocyanate (FITC)-conjugated goat immunoglobulin. Stained cells were washed three times and immediately analyzed on a FACScan (Becton Dickinson).

Immunoblot analysis

To assess total $\beta 4$ integrin levels, pooled populations of $\beta 4$ integrin and vector control transfected or infected pooled cell populations were lysed in RIPA buffer (50 mM Tris-HCl [pH 7.4], 150 mM sodium chloride, 1% NP-40, 0.5% deoxycholate, 0.2% SDS containing 20 mM sodium fluoride, and 1 mM sodium orthovanadate, and a cocktail of protease inhibitors). Equal amounts

of protein were separated on nonreducing SDS-PAGE gels, immunoblotted, and detected with an ECL system (Amersham Pharmacia BioTech).
